GENERALIZED ALON-BOPPANA THEOREMS AND ERROR-CORRECTING CODES

JOEL FRIEDMAN* AND JEAN-PIERRE TILLICH†

Abstract. In this paper we describe several theorems that give lower bounds on the second eigenvalue of any quotient of a given size of a fixed graph, $G$. These theorems generalize Alon-Boppana type theorems, where $G$ is a regular (infinite) tree.

When $G$ is a hypercube, our theorems give minimum distance upper bounds on linear binary codes of a given size and information rate. Our bounds at best equal the current best bounds for codes, and only apply to linear codes. However, it is of interest to note that (1) one very simple Alon-Boppana argument yields non-trivial code bound, and (2) our Alon-Boppana argument that equals a current best bound for codes has some hope of improvement.

We also improve the bound in sharpest known Alon-Boppana theorem (i.e., when $G$ is a regular tree).

1. Introduction. The goal of this paper is to draw a connection between the “Alon-Boppana” bound, in the theory of expanders or graph eigenvalues, and asymptotic upper bounds for the minimum distance of an error-correcting code of a given rate.

Recall that the Alon-Boppana bound is a lower bound on the second eigenvalue of finite $d$-regular graphs. In its basic form it says that the second largest eigenvalue of a $d$-regular graph is greater than $2\sqrt{d-1} - o(1)$ as the number of vertices goes to infinity. In this paper we show that the Alon-Boppana bound can be generalized to finite quotients of a large class of graphs, $H$; in the original Alon-Boppana setting, $H$ is the $d$-regular infinite tree, which covers any (connected) $d$-regular graph. See [Fri03] for such results when $H$ is infinite and fixed.

The connection with upper bounds on the minimum distance of a binary linear code is that the minimum distance of a binary linear code $C$ can be expressed as a certain decreasing function of the second largest eigenvalue of a certain regular graph associated to $C$ (this graph is generally called the coset graph of $C^\perp$; see Section 5). In other words any lower bound on the second eigenvalue of this graph translates into an upper bound on the minimum distance of the code. If we use the aforementioned Alon-Boppana directly then we only obtain a very weak upper bound on the minimum distance of the code.

However, when we know more about the geometry of the graph, for instance lower bounds on the number of cycles of a given length, then the Alon-Boppana lower bound can be strengthened considerably. We derive several lower bounds by different techniques. The first one is derived through lower bounds on the number of cycles of a given length, the second through comparison with Dirichlet eigenvalues. There is however a common underlying idea, namely the notion of a covering graph (see Section 3). In both cases, the relevant quantities (either the number of cycles or the Dirichlet eigenvalues) are bounded by the corresponding quantities of a cover graph. The crux of this approach is that the cover graph may have a simple structure (for instance, for the coset graph we may choose a Boolean hypercube), which enables us to estimate these quantities directly.

The second technique, when applied to the graph associated to the coset graph of a binary linear code, yields the first MRRW bound [MRRW77] in coding theory, which is the best known upper bound on the minimum distance for low rate codes. This bound was originally obtained with the “linear programming” approach. While our approach has elements in common with the classical “linear programming” approach, we believe our approach is easier to use and suggests more geometrically visualizable questions on the Boolean hypercube. This is because a simple “Alon-Boppana” argument easily gives an interesting coding bound (see Section 5), and we don’t know of an analogous argument based on the linear programming approach. Also, in an attempt to improve the “first MRRW bound” (of [MRRW77], as explained in Section 2) there arises a geometric question about what is the correct analogue for the hypercube of the classical Faber-Krahn inequality for domains in \( \mathbb{R}^n \) (see, e.g., [Fab23, Kra25, Cha84, Fri93]); if this analogue is “asymptotically different” (see Section 10), which is presently conceivable, then the first MRRW bound will be improved. We must admit, however, that at present we cannot improve but only duplicate the first MRRW bound with our methods; furthermore it is quite conceivable that any theorem obtained with our methods could be translated into a proof based only on the linear programming approach (it would be interesting to know if this were really true). But we reiterate that even if our approach is, in a sense, subsumed by the linear programming approach, the setting and geometric pictures suggested by our method seems to be easier to work with. Moreover, we also show how to obtain the linear programming bounds dealing only with the Hamming space through our approach, by changing slightly one of our Alon-Boppana bounds (see Section 10).

The consequences for the classical Alon-Boppana theorem (i.e., for the second eigenvalue of a \( d \)-regular graph) in this paper is that we improve the best Alon-Boppana bound (of Friedman and Kahale, see [Fri93]) in the second order term by essentially a factor of four (see Section 9). This is done by generalizing the known Alon-Boppana bound techniques to give coding bounds, and realizing that the first MRRW bound improves this bound, in a sense, by a factor of two. It is not hard to see where this factor of two can be recovered—by “projecting out the constants” (see Sections 9 and 10). However, Kahale’s method (see [Kah93]) also “projects out the constants,” and our improvement to classical Alon-Boppana can also be obtained by a minor modification of Kahale’s proof.

2. A basic fact for obtaining Alon-Boppana bounds. Let us first introduce some general notation concerning eigenvalues of (adjacency matrices of) graphs. Let \( G \) be a graph with \( |V_G| = n \) and adjacency matrix \( A_G \). Recall that \( A_G \) is a \( n \times n \) symmetric matrix, with entries \( a_{uv} \) indexed by the vertices of the graph, and \( a_{uv} = 1 \) iff \( u \) and \( v \) are adjacent in \( G \), and \( a_{uv} = 0 \) otherwise. Since \( A_G \) is symmetric, it can be diagonalised in an orthonormal basis. Then we write

\[
\lambda_1(G) \geq \lambda_2(G) \geq \cdots \geq \lambda_n(G)
\]

for the eigenvalues of \( G \)’s adjacency matrix (written with their multiplicity). We denote by \( e_1, e_2, \ldots, e_n \) the corresponding (orthonormal) basis of eigenvectors. We write \( \rho_1 = \rho_1(G) \) for the \( i \)-th largest value that occurs among the \( |\lambda_i| \); for example, the Perron-Frobenius theorem implies that \( \rho_1 = \lambda_1 \) and thus

\[
\rho_2 = \rho_2(G) = \max(\lambda_2, -\lambda_n).
\]

Estimating \( \lambda_2 \) is of interest in studying expansion; however, some techniques only estimate \( \rho_2 \) (and higher \( \rho_i \)).
Rayleigh principle gives us the following characterization of $\lambda_2(G)$ (it is a straightforward consequence of the fact that $e_1, e_2, \ldots, e_n$ is an orthonormal basis)

$$\lambda_2(G) = \max_{f \neq e_1} \frac{(A_G f, f)}{(f, f)}$$  \hspace{1cm} (2.1)

If $G$ is a regular graph, then $e_1$ can be chosen to be $\frac{1}{\sqrt{n}} \mathbf{1}$, where $\mathbf{1}$ is the all ones vector, and therefore by applying the previous equation we obtain

**Fact 2.1.** If $G$ is a regular graph, and $f \in \mathbb{R}^n$ is orthogonal to $\mathbf{1}$ then

$$\lambda_2(G) \geq \frac{(A_G f, f)}{(f, f)}$$  \hspace{1cm} (2.2)

This inequality is the key to obtain lower bounds on $\lambda_2(G)$: by choosing $f$ appropriately we can relate $\lambda_2(G)$ to other quantities of the graph. Notice that we can also apply the Rayleigh principle to $A_l G$ (or even sometimes to a well chosen polynomial applied to $A_G$), this yields for $f \perp \mathbf{1}$ and any positive odd integer $l$:

$$\lambda_2(G)^l \geq \frac{(A_l G f, f)}{(f, f)}$$  \hspace{1cm} (2.3)

and in general for any positive integer $l$:

$$\rho_2(G)^l \geq \frac{(A_l G f, f)}{(f, f)}$$  \hspace{1cm} (2.4)

In what follows we are going to apply these simple facts to several different choices of $f$. For all these choices we are going to control the term $\frac{(A_l G f, f)}{(f, f)}$ that appears on the right-hand-side through the notion of a cover graph.

### 3. Graphs and Covers.

In this section we review the definition of graph covers. Until Section 11 we assume all graphs are *simple*, i.e. have no multiple edges or self-loops; this simplifies the discussion and notation. In Section 11 we give the definitions needed for general graphs; all theorems immediately carry over to general graphs.

By a *simple graph* we mean a graph with no multiple edges or self-loops; so we may think of a simple graph, $G$, as a pair $(V_G, E_G)$ where $E_G$ is a subset of the set of unordered pairs of $V_G$. Until Section 11 we understand a graph to mean a simple graph.

A morphism $\pi : H \rightarrow G$ of graphs is a map from $V_H$ to $V_G$ such that the natural map from $E_H$ onto pairs in $V_G$ has its image in $E_G$. $\pi$ thus gives rise to a map from $E_H$ to $E_G$ which we also denote by $\pi$, assuming no confusion will arise.

A morphism $\pi : H \rightarrow G$ is called a covering map if for every edge $e = \{u, v\}$ of $G$ and every $u' \in V_H$ with $\pi(u') = u$ there is a unique $v' \in \pi^{-1}(v)$ such that $\{u', v'\}$ is an edge in $E_H$. We also say that in this case $H$ is a *cover* of $G$.

**Example 3.1.** Let $G$ be any finite graph. Then $G$ has a universal cover, $\pi : T \rightarrow G$, in that for any covering map $\nu : K \rightarrow G$ there is a covering map $\mu : T \rightarrow K$ such that $\pi = \nu \circ \mu$. $T$ is a tree. If $G$ is $d$-regular, i.e. each row and column of $A_G$ sums to $d$, then $T$ is a $d$-regular tree (and any two $d$-regular trees are isomorphic).

---

1This covering map, $\mu$, is uniquely defined if one works with “base-pointed graphs,” i.e. graphs with a distinguished vertex.
Example 3.2. Let $G$ be a connected Cayley graph on $(\mathbb{F}_2)^k$ of degree $n$, with generators $c_1, \ldots, c_n$. This is a graph where we connect any $x \in (\mathbb{F}_2)^k$ to $x + c_i$ for $i \in \{1, 2, \ldots, n\}$. Let $\mathbb{B}^n$ be the Boolean $n$-hypercube, i.e. the Cayley graph on $(\mathbb{F}_2)^n$ with generators $e_1, \ldots, e_n$ where $e_i$ is the $i$-th standard basis vector, i.e., $e_i$ is 0 on each coordinate except the $i$-th, where it is 1. Consider the map $\pi_{\text{lin}} : (\mathbb{F}_2)^n \rightarrow (\mathbb{F}_2)^k$ which takes $e_i$ (as above) to $c_i$ and is extended by linearity. Then $\pi_{\text{lin}}$ induces a covering map $\pi : \mathbb{B}^n \rightarrow G$.

4. Coding Theory. A code of length $n$ is a subset $C \subset (\mathbb{F}_2)^n$, where $\mathbb{F}_2 = \{0, 1\}$ is the field with two elements. $C$ is linear if it is a subspace of the vector space $(\mathbb{F}_2)^n$. We endow $(\mathbb{F}_2)^n$ with the Hamming distance, i.e. for $x, y \in (\mathbb{F}_2)^n$, $d(x, y)$ is the number of coordinates on which $x$ and $y$ differ. The minimum distance of a code, $C$, is

$$d_{\text{min}}(C) = \min\{d(x, y) \mid x, y \in C, x \neq y\},$$

and its normalized minimum distance is

$$\delta(C) = d_{\text{min}}(C)/n.$$ 

The information rate of a code is

$$R(C) = \frac{\log_2 |C|}{n}.$$ 

If $C$ is a linear code then this is just $(\dim C)/n$.

Let $\delta_{\text{max}}$ be the function

$$\delta_{\text{max}}(R) = \lim_{n \rightarrow \infty} \max\{\delta(C) \mid R(C) \geq R, C \subset (\mathbb{F}_2)^n\}$$

and

$$R_{\text{max}}(\delta) = \lim_{n \rightarrow \infty} \max\{R(C) \mid \delta(C) \geq \delta, C \subset (\mathbb{F}_2)^n\}.$$ 

We are interested in estimating these functions.

To estimate $\delta_{\text{max}}$ is essentially the same as to estimate $R_{\text{max}}$, but a bit of care is required to make this precise.

Proposition 4.1. Let $\delta_{\text{max}}(\alpha) \leq f(\alpha)$ for a continuous, strictly decreasing function, $f$, defined on an open interval. Then $(f^{-1}$ is defined on the image of $f$ and) $R_{\text{max}}(\delta) \leq f^{-1}(\delta)$.

Proof. This is an easy (but mildly annoying) technicality; see appendix B. \qed

We now state some classical bounds.

Theorem 4.2. $R_{\text{max}}(\delta) \geq 1 - h(\delta)$, where

$$h(\theta) = -\theta \log_2 \theta - (1 - \theta) \log_2 (1 - \theta).$$

Proof. See the asymptotic Gilbert-Varshamov bound in [vL99]. \qed
The best upper bound on $R_{\text{max}}$ is given by the following theorem:

**Theorem 4.3.**

$$R_{\text{max}}(\delta) \leq \min_{u \in [0, 1-2\delta]} b(u, \delta),$$  \hspace{1cm} (4.1)

where

$$b(u, \delta) = 1 + g(u^2) - g(u^2 + 2\delta u + 2\delta).$$

with

$$g(x) = h\left(\frac{1}{2} - \frac{\sqrt{1-x}}{2}\right).$$

For $\delta \geq 0.273$ this bound is the same as

$$R_{\text{max}}(\delta) \leq b(1 - 2\delta, \delta) = h\left(\frac{1}{2} - \sqrt{\delta(1-\delta)}\right).$$  \hspace{1cm} (4.2)

**Proof.** See [MRRW77] (or [MS77] for the latter half of the theorem).

The inequality (4.1) is known as the “second MRRW” bound; (4.2) is known as the “first MRRW” bound.

**Corollary 4.4.** For small $\alpha$ we have

$$\frac{1}{2} - (1 + o(1))\sqrt{\frac{\alpha}{2\log_2 e}} \leq \delta_{\text{max}}(\alpha) \leq \frac{1}{2} - (1 + o(1))\sqrt{\frac{\alpha}{\log_2(1/\alpha)}}.$$

The inequality (4.1) is known as the “second MRRW” bound; (4.2) is known as the “first MRRW” bound.

**Corollary 4.4.** For small $\alpha$ we have

$$\frac{1}{2} - (1 + o(1))\sqrt{\frac{\alpha}{2\log_2 e}} \leq \delta_{\text{max}}(\alpha) \leq \frac{1}{2} - (1 + o(1))\sqrt{\frac{\alpha}{\log_2(1/\alpha)}}.$$

**5. Codes and Eigenvalues.** In this section we recall how a graph can be associated to a linear code in such a way that the eigenvalues of the graph are in relationship with the codeword weights.

Let $C \subset (F_2)^n$ be a linear code with basis $r_1, \ldots, r_k$. We form the generator matrix, $M$, over $F_2$, whose rows are the $r_i$'s; so $M$ is an $k \times n$ matrix. Its columns, $c_1, \ldots, c_n$, can each be viewed as an element of $(F_2)^k$.

Let $G$ be the Cayley graph on $(F_2)^k$ with generators $c_1, \ldots, c_n$. Apparently $G$ may depend on the choice of the basis $r_1, r_2, \ldots, r_k$. It turns out that $G$ only depends on $C$. This can be seen by bringing in the dual code $C^\perp$ of $C$, that is

$$C^\perp = \{x \in (F_2)^n \mid x \cdot c = 0 \quad \forall c \in C\}.$$

Consider the graph with vertices the cosets $x + C^\perp$, and two cosets being linked by an edge if they are at Hamming distance 1. We claim that the Cayley graph defined before and this new graph are isomorphic, the isomorphism being given by the map $\pi : x + C^\perp \to Mx$. Indeed, let two cosets $x + C^\perp$ and $y + C^\perp$ be linked by an edge. This means that there exists $c \in C^\perp$ and $i \in \{1, \ldots, n\}$ such that $x = y + c + e_i$ (where $e_i$ is the $i$-th standard basis vector of $F_2^n$, i.e., $e_i$ is 0 on each coordinate except the $i$-th, where it is 1), this implies that $Mx = My + c_i$. On the other hand if $Mx = My + c_i$ then necessarily $x$ and $y + e_i$ differ only by an element of $C^\perp$.

---

2We shall assume (until Section 11) that no $c_i$’s vanish and the $c_i$’s are all distinct; if not, then $G$ will have self-loops and/or multiple edges, and we technically need Section 11 before we can apply our theory.
We say that this graph is the coset graph of $C^\perp$ or of the code $C$. The following is a well-known folk theorem (see [DS91] and the reference there):

**Theorem 5.1.** Let $\lambda_1 \geq \lambda_2 \geq \cdots$ be the eigenvalues of the adjacency matrix of the coset graph of $C^\perp$ arranged in non-increasing order. Then $\lambda_1 = n$ and $\lambda_2 = n - 2d_{\text{min}}(C)$. Moreover, the weights (i.e., distances to the zero code word) appearing in $C$ are just the $(n - \lambda_i)/2$ as $i$ ranges from 1 to $2^k$.

6. A Simple Generalized Alon-Boppana Theorem. In this section we give a very simple but rather weak generalized Alon-Boppana theorem and discuss its implications. Let $G$ be a $d$-regular graph. We use the approach outlined in Section 2 to obtain a lower bound on $\lambda_2(G)$ and $\rho_2(G)$ and we choose $f = \chi_u - \chi_v$ where $\chi$ denotes the characteristic function in (2.4). Notice that

$$(A_G^l \chi_u, \chi_u) = N_l(u), \quad (A_G^l \chi_v, \chi_v) = N_l(v),$$

where $N_l(v)$ denotes the number of walks of length $l$ from $v$ to itself. Moreover if $u$ and $v$ are at distance greater than $l \geq 0$, then

$$(A_G^l \chi_u, \chi_v) = (A_G^l \chi_v, \chi_u) = 0.$$

Hence

$$(A_G^lf, f) = N_l(u) + N_l(v)$$

Let $N_l = N_l(G)$ denote the minimum of $N_l(v)$ ranging over all vertices $v$ of the graph. Of course, $(f, f) = 2$, and so

$$(A_G^lf, f) \geq N_l(G).$$

By using (2.4) we now obtain

$$\rho(A_G) \geq (N_l)^{1/l};$$

The right-hand-side term can be estimated through a cover $H$ of $G$ for which the calculation of $N_l(H)$ might be much simpler. Indeed the following is clear.

**Fact 6.1.** If $\pi : H \to G$ is a cover, then any $H$ cycle about a vertex $v$, gives rise to a unique $G$ cycle about $\pi(v)$. Hence for any positive integer $l$ we have

$$N_l(G) \geq N_l(H).$$

In other words we have proved the following.

**Theorem 6.2.** Let $G$ be a $d$-regular graph that contains two vertices of distance $> l$ and $H$ be a cover of $G$. Then

$$\rho(A_G) \geq (N_l(H))^{1/l};$$

furthermore, if $l$ is odd then the above equation holds with $\rho$ replaced by $\lambda_2$.

---

This is the graph of cosets of the hypercube modulo $C^\perp$, or of $C^\perp$ cosets, but it is the graph of cosets one uses when working with $C$. Since we do not work with a code, $C$, and its dual, $C^\perp$, simultaneously (in this paper), no confusion will occur in referring to the graph as the coset graph of “the code.”

6
The last statement follows by using (2.3) instead of (2.4).

The above theorem is quite simple. Unfortunately, for some purposes, such as coding theory, we are interested in $\lambda_2(A_G)$ and the cover graph $H$ (which can be chosen to be a boolean hypercube) will be bipartite (i.e. $N_l(H) = 0$ for $l$ odd). So we prove the following variant of the above theorem.

**Theorem 6.3.** Let $\pi: H \to G$ be a covering map. Let $e_1, e_2$ be two edges of distance $> l$ (i.e. the distance from any of $e_1$’s endpoints to any of $e_2$’s is greater than $l$). Then

$$\rho(A_G) \geq \left( N_l(H) + N_{l-1}(H) \right)^{1/l};$$

Furthermore, if $l$ is odd then the above equation holds with $\rho$ replaced by $\lambda_2$.

**Proof.** Let $e_i = \{u_i, v_i\}$ and set

$$f = \chi_{u_1} + \chi_{v_1} - \chi_{u_2} - \chi_{v_2}.$$  

We have that $(A^l \chi_{u_1}, \chi_{v_1})$ is at least $N_{l-1}(H)$, since any walk of length $l-1$ beginning and ending in $u_1$ yields a walk from $u_1$ to $v_1$ with one additional step. Similar reasoning to that in the previous theorem then yields:

$$(A^lf, f) \geq 4(N_l(H) + N_{l-1}(H)), $$

and, of course, $(f, f) = 4$. Similar reasoning as before now yields this theorem. 

We state two corollaries of this simple theorem:

**Corollary 6.4.** Fix $d$. Then for any $d$-regular graph, $G$, on $n$ vertices, we have $\rho(G) \geq 2\sqrt{d-1} - o(1)$ as $n \to \infty$.

This follows by taking $H$ to be the universal cover of $G$ (namely the infinite $d$-regular tree) and by noticing that any $d$-regular graph on $n$ vertices has at least two vertices which are at distance $\lceil \log_{d-1} n \rceil$. The relevant computation can be found in [LPS88] for instance.

We get stronger bounds with regular graphs which admit a cover which has more closed walks than the $d$-regular infinite tree, and this is exactly what happens for the coset graph of a code of length $n$ which admits the boolean hypercube as a cover (see Example 3.2)

**Corollary 6.5.** Let $C$ be a binary linear code of length $n$ of rate $\leq R$. The normalized minimum distance of $C$, $\delta$, satisfies $\delta \leq f(R)$, where $f$ is a function that satisfies:

$$f(R) = \frac{1}{2} - C(1 + o(1))\sqrt{R \log_2 R}$$

when $R$ tends to $0$, with $C = 1/\sqrt{4e}$.

The bound of [MRRW77] yields the same corollary but with $C = 1$. The calculation which lead to this theorem are in Appendix A.

**7. Projecting out constants.** In this section we introduce a technique that will strengthen essentially all of our Alon-Boppana theorems, including the ones in the previous section and the more refined theorems to come.

In the previous section we created functions, $f$, for which $(A^lf, f)$ could be bounded; the idea was to concentrate $f$ at a few vertices. Since it is important
that \( f \) be orthogonal to \( \bar{1} \), the all ones vector, we took \( f \) to have as many positive values as negative values, taking the values of different sign to be far apart (a distance > \( l \)). However, we may alternatively take \( f \) to be all positive, provided that we then remove \( f \)'s component in the direction of \( \bar{1} \). This is the same as taking \( f \) to be concentrated and positive, subtracting the same (small) negative value at every other vertex.

The idea of choosing an arbitrary \( f \) and “projecting out the constant component” will be used repeatedly in this paper. Here is this technique applied to Theorem 6.2.

**Theorem 7.1.** Let \( \pi : H \to G \) be a covering map. Let \( G \) be a \( d \)-regular graph, and let \( l \) be a value such that

\[
N_l(H) = d^l/|V_G|.
\]

Then

\[
\rho(A_G) \geq \left( N_l(H) - \frac{d^l}{|V_G|} \right)^{1/l};
\]

furthermore, if \( l \) is odd then the above equation holds with \( \rho \) replaced by \( \lambda_2 \).

**Proof.** Fix any \( v \in V_G \) and set \( f = \chi_v \). Then \( \bar{f} = f - \bar{1}/|V_G| \) is orthogonal to \( \bar{1} \).

We have

\[
(A^l \bar{f}, \bar{f}) = (A^l f, f) - (A^l \bar{1}/|V_G|, \bar{1}/|V_G|) \geq N_l(H) - d^l/|V_G|,
\]

and

\[
(\bar{f}, \bar{f}) = (f, f) - (\bar{1}/|V_G|, \bar{1}/|V_G|) \leq 1.
\]

The reasoning used at the end of Theorem 6.2 now applies here, and we conclude the theorem. \( \square \)

We may also obtain the following variant of Theorem 6.3.

**Theorem 7.2.** Let \( \pi : H \to G \) be a covering map with \( G \) a \( d \)-regular graph, and let \( l \) be a value such that

\[
N_l(H) + N_{l-1}(H) \geq 2d^l/|V_G|.
\]

Then

\[
\rho(A_G) \geq \left( N_l(H) + N_{l-1}(H) - \frac{2d^l}{|V_G|} \right)^{1/l},
\]

furthermore, if \( l \) is odd then the above equation holds with \( \rho \) replaced by \( \lambda_2 \).

**Proof.** Fix any edge, \( e = \{u, v\} \), and let \( f = \chi_u + \chi_v \) and \( \bar{f} = f - 2\bar{1}/|V_G| \). As before, \( \bar{f} \) is orthogonal to \( \bar{1} \), and we have

\[
(A^l \bar{f}, \bar{f}) = (A^l f, f) - 4(A^l \bar{1}/|V_G|, \bar{1}/|V_G|) \geq 2N_l(H) + 2N_{l-1}(H) - 4d^l/|V_G|,
\]

and

\[
(\bar{f}, \bar{f}) \leq 2.
\]

We argue as before. \( \square \)

Using this theorem we improve Corollary 6.5 by a factor of 2, as follows; see Appendix A for the proof.

**Corollary 7.3.** In Corollary 6.5, we may take \( C = 1/\sqrt{2e} \).
8. Eigenfunction Pushing Techniques. Let us now apply (2.2) to functions of the form $\tilde{f} = f - c\bar{1}$ (where $c$ is chosen such that $\tilde{f}$ is orthogonal to $\bar{1}$) where $f$ is a function supported on a subset $U$ of vertices of the graph (this means that $f$ is equal to 0 outside of $U$). We easily obtain the following.

**Proposition 8.1.** Let $f$ be supported on a set, $U$. Let $G$ be $d$-regular. Then

$$\lambda_2(G) \geq \frac{(A_G f, f)}{(f, f)} - \frac{d|U|}{|V_G|}.$$ 

**Proof.** Let $\tilde{f} = f - c\bar{1}$ where $c = (f, \bar{1})/|V_G|$; then $\tilde{f}$ is orthogonal to $\bar{1}$, and so

$$\lambda_2(G) \geq \frac{(A_G \tilde{f}, \tilde{f})}{(f, f)}. \tag{8.1}$$

Since

$$(f, \bar{1})^2 = (f, \chi_U)^2 \leq (f, f)(\chi_U, \chi_U) = (f, f)|U|,$$

we have

$$(A_G \tilde{f}, \tilde{f}) = (A_G f, f) - d\bar{c}^2|V_G| \leq (A_G f, f) - d(f, f)|U|/|V_G|.$$ Combining this with the fact that $(\tilde{f}, \tilde{f}) \leq (f, f)$ (since $\tilde{f}$ is a projection of $f$ onto the subspace orthogonal to $\bar{1}$) and with the inequality (8.1), finishes the proposition. \qed

To optimize this inequality we have to find for a given subset of vertices $U$ the function $f$ which maximizes the ratio $\frac{(A_G f, f)}{(f, f)}$. This maximum is known as a Dirichlet eigenvalue. We define for a graph $G$ and a subset of vertices $W \subset V_G$,

$$\lambda_{1,\text{Dir}}(W) = \max_{f \in C_0(W)} \frac{(Af, f)}{(f, f)},$$

where we write $C_0(W)$ for those functions supported in $W$. It is easy to check that the maximum is attained for a non-negative function (this is a simple consequence of the Perron-Frobenius theorem, see also [Fri93]). The $f$ achieving the above maximum is called the first Dirichlet eigenfunction of $A$; this $f$ is known to satisfy $Af = \lambda f$ for $\lambda = \lambda_{1,\text{Dir}}(W)$ (see [Fri93]).

Then it makes sense to find the subset $W$ of a given size which maximizes this eigenvalue, this leads us to define for $a > 0$, $\text{FK}_G(a)$, the Faber-Krahn maximum of size $a$ as

$$\text{FK}_G(a) = \max_{|W| \leq a} \lambda_{1,\text{Dir}}(W);$$

the $W$ achieving this maximum is the Faber-Krahn maximizer of size $a$.

The nice thing about this quantity is that it has a lower bound in terms of the Faber-Krahn maximum for the same size of a cover graph, that is

**Theorem 8.2.** Let $H$ be a cover of $G$. Then

$$\text{FK}_H(a) \leq \text{FK}_G(a).$$
To prove this fact we need a lemma and a definition. For a covering map $\pi: H \to G$ and $f: V_H \to \mathbb{R}$, we define the *push forward*, $\pi_* f$, a function on $V_G$, whenever $H$ is finite, via

$$(\pi_* f)(v) = \sum_{\pi(w) = v} f(w).$$

**Lemma 8.3.** Let $f \in C(V_H)$ and let $\pi: H \to G$ be a covering map. Assume $H$ is finite. If $f \geq 0$ everywhere, then also $\pi_* f \geq 0$. If $A_H f \geq \lambda f$ everywhere, for some real $\lambda$, then also $A_G \pi_* f \geq \lambda \pi_* f$. If $f$ is supported in $W$, then $\pi_* f$ is supported in $\pi(W)$.

**Proof.** The first part (the non-negativity statement) is clear. The second part follows from the fact that $\pi$ is a local isomorphism. The third part is also clear.\hfill $\Box$

We are ready now to prove Theorem 8.2.

**Proof.** of Theorem 8.2 Let $FK_H(a) = \lambda = \lambda_{\text{Dir}}(W)$ be the minimizing eigenvalue with $|W| = a$, and let $f$ be the corresponding eigenfunction. Then $\pi_* f$ satisfies $A_G (\pi_* f) \geq \lambda \pi_* f$ and $\pi_* f$ is non-negative and supported on $\pi(W)$, so

$$\lambda_{\text{Dir}}(\pi(W)) \geq \frac{(A_G \pi_* f, \pi_* f)}{(\pi_* f, \pi_* f)} \geq \frac{(\lambda \pi_* f, \pi_* f)}{(\pi_* f, \pi_* f)} \geq \lambda.$$ 

Furthermore $\pi(W)$ is a set of size at most $a$. Hence

$$FK_G(a) \geq \lambda = FK_H(a).$$

\hfill $\Box$

Putting Proposition 8.1 and Theorem 8.2 together we obtain

**Theorem 8.4.** Let $G$ be a $d$-regular graph, and $H$ be a cover of $G$. Then

$$\lambda_2(A_G) \geq FK_H(a) - \frac{da}{|V_G|}.$$ 

For an application to coding theory we observe:

**Proposition 8.5.** Let $H$ be the $n$-dimensional hypercube. Then for $\alpha \in (0,1)$ fixed we have $FK_H(2^{\alpha n}) \geq 2\sqrt{\gamma(1-\gamma)n} + o(n)$, where $\alpha = H_2(\gamma)$.

**Proof.** We take a ball of size roughly $2^{\alpha n}$. For the details see appendix C.\hfill $\Box$

Notice that we could also give a simple bound of $FK_H(2^{\alpha n}) \geq \alpha n$ by taking the characteristic function of a subcube of dimension $\alpha n$.

A corollary is the first MRRW bound.

**Corollary 8.6.** For any $\delta \in (0,1)$ we have

$$R_{\text{max}}(\delta) \leq h\left(1/2 - \sqrt{\delta(1-\delta)}\right).$$

**Proof.** Fix an $\alpha \in (0,1)$ and a code $C$ of information rate $\geq \alpha$ and a corresponding covering map $\pi: H \to G$ We apply Theorem 8.4 with $a = 2^{\alpha n}/\log n$. We conclude

$$\lambda_2(A_G) \geq 2\sqrt{\gamma(1-\gamma)} + o_n(1)$$
where $\alpha = h(\gamma)$. Hence

$$\delta \leq 1/2 - \sqrt{\gamma(1 - \gamma)},$$

and so

$$\gamma \leq 1/2 - \sqrt{\delta(1 - \delta)}$$

and the corollary follows.

\[\square\]

**Remark 8.7.** Notice that a (sub)cube of dimension $\alpha n$ has largest adjacency eigenvalue $\alpha n$. This implies that $\text{FK}_{H}(2^{\alpha n}) \geq \alpha n$. This gives the weak corollary that $\alpha_{\text{max}}(\delta) \leq (1 - \delta)/2$, which agrees asymptotically with the Plotkin and Griesmer bounds of coding theory (see [vL99]).

**Remark 8.8.** The approach which was used in this section borrows some ideas from [Nil91, Fri93]. Assume that $G$ has a cover graph $H$. If $f_{H}$ is a non-negative “approximate eigenfunction” on $H$, we can try to form “versions” of it, $f_{G}$, on a quotient, $G$, with similar properties. In this section we have formed our version on $G$ by “summing over fibres” (this was the push forward function defined above); this is a similar technique to that used by Nilli (see [Nil91]), later refined by Friedman and Kahale (see [Fri93])\(^4\). Our improvement on this technique was obtained by “projecting out the constants,” meaning that we project out the $\overline{I}$ component from $f_{G}$ rather than setting up $f_{G}$ (or $f_{H}$) with a matching non-positive component to make it orthogonal to $\overline{I}$ (as done by Nilli, Friedman, and Kahale). We explain how this improves the classical Alon-Boppana bound in the next section.

9. Classical Alon-Boppana. In this section we comment on how to improve the classical Alon-Boppana theorem by a constant factor in the second order term. The bounds as derived in [Nil91],[Fri93], and [Kah93] all come up with a function, $f$, orthogonal to the constant function, whereupon we estimate $R(f)$ and use $\lambda_{2} \geq R(f)$. In all cases, and in this paper, the following construction is involved: for a vertex, $u$, and distance $r$, we consider a function $g = g_{u;r}$ that (1) vanishes on vertices of distance greater than $r$ to $u$, and (2) is constructed either as a radial function (a function of the distance) with respect to $u$, or is the push forward of a radial function of a lift of $u$ on the universal cover, the infinite, $d$-regular tree (see also the comments at the end of Section 8); therefore $g$ is non-negative. (In a sense, the “optimal” $g$ to take is the Dirichlet eigenfunction on the tree, as in [Fri93].) There are two approaches to constructing $f$ from these $g$’s.

The first approach is to take two vertices, $u, v$, of large distance apart, to take $r$ with $g_{u;r}, g_{v;r}$ of disjoint support, and to form $f$ as a difference of appropriate positive multiples of $g_{u;r}$ and $g_{v;r}$. Here $r$ is roughly $(1/2) \log_{d-1} n$. This approach is taken in [Nil91] and [Fri93].

The second approach is to take one vertex, $u$, and to form $f$ by taking $g_{u;r'}$ and project out the constants. In this case $r'$ can be taken to be as large as $\log_{d-1} (n/\omega(n))$, where $\omega(n)$ is any function with $\omega(n)/\log^{2} n \rightarrow 0$ as $n \rightarrow \infty$. So $r'$ is roughly twice as

\[^{4}\text{Actually, the previous technique (of Nilli, Friedman, and Kahale) takes radial functions on $G$ given by the radial function on $H$ that gives the first Dirichlet eigenfunction of a ball in $H$ of a given radius. The technique used here “pushed down” the eigenfunction on $H$ to $G$ by summing over the fibres, i.e. for each vertex, $v \in V_{G}$ we sum the eigenfunction over $\pi^{-1}(v)$. This may be better suited in certain situations, e.g. when the graphs are not regular.}\]
large as \( r \), which gives an improvement by a factor of four in the second order term. For example, in [Fri93] we have a bound of

\[
\lambda_2 \geq 2\sqrt{d-1} \left(1 - c \log_{d-1}^2 n + O(\log \log n \log^{-3} n)\right),
\]

where \( c = 2\pi^2 \). The projecting technique improves this to \( c = \pi^2 / 2 \). This projecting technique was used by Kahale in [Kah93]; he did not estimate \( c \) explicitly, although his choice of parameters in the proof gives \( c = 2\pi^2 \) (as in [Fri93]); however it is easy to modify Kahale’s choice of parameters (i.e., choose \( l \) to be the floor of \( \log_{d-1} (n \log^3 n) \) in his proof of Corollary 1 in Section 3) to obtain \( c = \pi^2 / 2 \).

We now state the improved classical Alon-Boppana bound in a theorem.

**Theorem 9.1.** Let \( d \) be fixed. For any \( d \)-regular graph on \( n \) vertices we have equation (9.1) holds with \( c = \pi^2 / 2 \).

**Proof.** We give two proofs, omitting some minor calculations. The first is to modify Kahale’s proof as described above. The second proof is to apply Theorem 8.4 with \( H \) the \( d \)-regular tree and \( \alpha \) being the floor of \( n / \log^3 n \). We remark that FK(\( H \)) is at least that of the first Dirichlet eigenvalue of a ball in \( H \) of size at most \( a \). Proposition 3.2 of [Fri93] computes this eigenvalue exactly. This changes the value of \( k \) in Proposition 3.7 of [Fri93] (which is the radius of the ball to which Proposition 3.2 of [Fri93] is applied) from \((1/2) \log_{d-1} n\) to essentially double that, i.e., the floor of \( \log_{d-1} (n / \log^3 n) \). Thus the second order term of \( 2\sqrt{d-1} \pi^2 / (2k^2) \) essentially gets multiplied by \( 1 / 4 \) (up to higher order terms). The only additional term here is the \( da / |V_G| \) term in Theorem 8.4; this term is \( O(\log^{-3} n) \) by our choice of \( a \).

\[ \square \]

10. A Stronger Alon-Boppana Bound.

**10.1. A Simple Improvement.** In this subsection we give an example of a more general generalized Alon-Boppana bound. Namely, the following theorem and corollary strengthen Proposition 8.1.

**Theorem 10.1.** Let \( G \) be a \( d \)-regular graph and let \( p \) be any real-valued function defined on the eigenvalues of \( A_G \). Then

\[
(f, f) \max_{i \geq 2} p(\lambda_i) \geq (p(A_G)f, f) - p(d)(f, \tilde{1})^2 / |V_G|,
\]

The theorem follows immediately from the spectral decomposition on \( A_G \) as applied to \( f \).

**Corollary 10.2.** If in addition to the hypothesis in the above theorem we have \( f \) is supported in \( U \), then

\[
(f, f) \max_{i \geq 2} p(\lambda_i) \geq (p(A_G)f, f) - p(d)(f, f)|U| / |V_G|.
\]

The special case \( p(x) = x \) was the bound used in the previous section. When \( G \) has a cover which is distance regular, then there is a very natural choice of polynomials in the corollary which enables to have some control on the term \( (p(A_G)f, f) \) when \( f = \chi_v \) for any vertex \( v \) of \( G \). Indeed, let \( H \) be a distance regular cover of \( G \). Let \( D \) denote the diameter of \( H \). Then there are \( D + 1 \) polynomials \( P_0, P_1, P_2, \ldots, P_D \) (see [BCN89]) such that \( P_i(A_H) \) is the adjacency matrix of the graph with the same vertices as \( H \) and two vertices are joined by an edge iiff they are at distance \( i \) in \( H \). In such a setting for any \( Q = \sum_{i=0}^D \beta_i P_i \) where the \( \beta_i \)'s are nonnegative we have
that \((Q(A_G)\chi_v, \chi_v) \geq (Q(A_H)\chi_v, \chi_v)\). Notice now that \((Q(A_H)\chi_v, \chi_v) = \beta_0\) and therefore

\[(Q(A_G)\chi_v, \chi_v) \geq \beta_0. \tag{10.1}\]

The coset graphs associated to a binary linear code of length \(n\) that we consider in this article have a common cover which is distance regular namely the boolean cube \(B^n\). An application of the aforementioned remark leads to the Delsarte linear programming bound in coding theory as explained in the following subsection.

10.2. Connections with the Delsarte Approach. Let us first quickly review the linear programming approach for obtaining upper bounds on the minimum distance of a code (see [MS77, vL99] for more details). For a code \(C \in (F_2)^n\), we consider the distance distribution of the code, i.e. the \(B_i\)'s for \(i = 0, \ldots, n\), where \(B_i\) denotes the average number of codewords of distance \(i\) to a fixed codeword, that is \(B_i = \frac{1}{n} |\{(x, y) : x \in C, y \in C, d(x, y) = i\}|\). The linear programming bound is based on the inequality

\[
\sum_{i=0}^{n} B_i K_k(i) \geq 0
\]

for \(k \in \{0, 1, \ldots, n\}\), where \(K_k\) is a Krawtchouk polynomial of degree \(k\) :

\[
K_k(x) \defeq \sum_{j=0}^{k} (-1)^j \binom{x}{j} \binom{n-x}{k-j},
\]

with \(\binom{x}{j} \defeq \sum_{j=0}^{x} \sum_{j=0}^{x-j+1} \binom{x}{j} \binom{x-j+1}{j}\). This yields linear inequalities which should be satisfied by the \(B_i\)'s. By maximizing the sum of the \(B_i\)'s (which is equal to the size of the code) which satisfy these inequalities we obtain a linear programming problem for which an upper bound can be found by duality. This duality result can be written as (see [vL99] Theorem 5.3.5)

**Theorem 10.3.** Let \(\beta(x) = 1 + \sum_{k=1}^{n} \beta_k K_k(x)\) be any polynomial with \(\beta_k \geq 0\) \((1 \leq k \leq n)\) such that \(\beta(j) \leq 0\) for \(j = d, d + 1, \ldots, n\) then any code of minimum distance \(\geq d\) and length \(n\) has cardinality at most \(\beta(0)\).

Finding interesting choices for \(\beta\) turns out to be a nontrivial task, however the first MRRW bound can be obtained by a direct application of this theorem by choosing \(\beta\) appropriately (see [vL99]).

We now claim that this theorem is a simple consequence of Corollary 10.2, provided we restrict to linear codes. Indeed, if we let \(P_k \defeq K_k((n-x)/2)\), then \(P_k(A_{B^n})\) is nothing but the adjacency matrix of the graph with vertices belonging to \(F_2^n\) and two vertices being adjacent iff they are at Hamming distance \(k\). This follows immediately from classical results about the Hamming association scheme (see for instance Chapter 21 in [MS77]). Therefore by using the remark which follows Corollary 10.2 for any polynomial \(Q(x) = 1 + \sum_{k=1}^{n} \beta_k P_k(x) = 1 + \sum_{k=1}^{n} \beta_k K_k((n-x)/2)\) with \(\beta_k \geq 0\) we have that for any vertex of the coset graph \(G\) of a binary linear code of length \(n\)

\[(Q(A_G)\chi_v, \chi_v) \geq 1. \tag{10.2}\]

Notice now that by Theorem 5.1 \(P_k(\lambda_i) = K_k(j)\) for some integer \(j \in [d_{\min}(C), n]\) for any eigenvalue of the adjacency matrix of \(G\) different from \(n\). Therefore \(Q(\lambda_i) = \)
1 + \sum_{k=1}^{n} \beta_k K_k(j). This implies that

\[(\chi_v, \chi_v) \max \{Q(\lambda_i) | 2 \leq i \leq |V_G|\} \leq 0 \quad (10.3)\]

if \(Q\) has been chosen such that \(1 + \sum_{k=1}^{n} \beta_k K_k(j) \leq 0\) for any integer \(j \in [d_{\text{min}}(C), n]\)
(since this implies that \(Q(\lambda_i) \leq 0\) for \(i \in \{2, \ldots, |V_G|\}\)). We eventually obtain by using
Corollary 10.2 with \(f = \chi_v\) and by putting inequalities (10.3) and (10.2) together that

\[0 \geq 1 - \frac{1 + \sum_{k=1}^{n} \beta_k P_k(0)}{|C|}\]

since \(Q(n) = 1 + \sum_{k=1}^{n} \beta_k P_k(0)\) by Theorem 5.1 and \(|V_G| = |C|\). This proves Theorem 10.3.

11. General Graph Theory. In this section we review some basic terminology
and notions needed to generalize covering theory to graphs with multiple edges and/or self-loops.

11.1. Directed Graphs. By a directed graph we mean a pair of sets, \(G = (V_G, E_G)\), with an identification of \(E_G\) as a multi-set of \(V_G \times V_G\). In other words, \(G\) comes with an incidence map \(i_G: E_G \to V_G \times V_G\). We write \(i, E, V\) for \(i_G, E_G, V_G\) if no confusion can result. If \(i(e) = (u, v)\) we say that \(e\) is of type \((u, v)\) or that \(e\) originates in \(u\) and terminates in \(v\) or that \(e\)’s tail is \(u\) and \(e\)’s head is \(v\); in any case we will write \(e \sim (u, v)\): if no multiple edges occur, i.e. if \(i\) is injective, then we may
unambiguously write \(e = (u, v)\).

A walk is an alternating sequence of vertices and edges such that when \(\ldots, v, e, \ldots\)
ocurs in the sequence, \(e\)’s tail is \(v\), and similarly with the order of \(v, e\) reversed (with
“head” replacing “tail”). The adjacency matrix, \(A_G\), of a graph, \(G\), is the square
matrix indexed on \(V_G\) whose \(u, v\)-th entry counts how many edges have type \(u, v\). For
a positive integer, \(k\), the \(u, v\)-th entry of \((A_G)^k\) counts how many directed walks there
are from \(u\) to \(v\) of length \(k\). All this makes sense if \(V_G\) or \(E_G\) is infinite, although the
entries of \(A_G\) or \((A_G)^k\) may not be finite.

A morphism \(\pi: H \to G\) of directed graphs is a collection of maps \(\pi_V: V_H \to V_G\)
and \(\pi_E: E_H \to E_G\) that commutes with the incidence relations (i.e., \(i_G \circ \pi_E = \pi_V \times \pi_V \circ i_H\)). We often drop the subscripts from \(\pi_V, \pi_E\) if no confusion can result.

For a morphism of directed graphs, \(\pi: H \to G\), it is possible to give a number of
equivalent definitions for \(\pi\) to be a covering map: all definitions amount to \(\pi\) being
a local isomorphism in some sense. One definition is that for every vertex, \(v \in V_G, w\ in \pi^{-1}(v)\), and every edge \(e \in E_G\) with tail \(v\), there is exactly one \(f \in \pi^{-1}(e)\) whose
tail is \(w\), and similarly with “head” replacing “tail.” Another possibility is to define
the geometric realization of a graph (as in [Fri93]): then a covering map is a covering
map in the topological sense.

11.2. Graphs. By an undirected graph or simply a graph we mean a directed
graph, \(G\), with an involution\(^5\) \(i\) on \(E_G\) that reverses heads and tails; in other words,
\(G\)’s edges are paired, \(e \sim (u, v)\) with an edge \(i(e) \sim (v, u)\), where \(e\) may be paired
with itself\(^6\) if \(u = v\).

\(^5\)For \(i\) to be an involution means that \(i \circ i\) is the identity.

\(^6\)This gives rise to “half-loops,” which are edges paired with themselves, and “whole-loops” in
the language of [Fri93]. For example, a whole-loop contributes 2 to an entry on the diagonal of
the adjacency matrix, whereas a half-loop contributes 1.
A morphism of graphs is one of the underlying directed graphs that commutes with the $c$'s. A covering maps, adjacency matrices, and walks in graphs are just the same of the underlying directed graphs.

It is now simple to see that all the theorems of this paper could as well have been stated for graphs that may have self-loops or multiple edges.

12. Concluding Remarks. One of the most exciting questions to us is to find the Faber-Krahn maximizer and maximum of the hypercube. One can find examples\footnote{For example, in the 3-hypercube, the 2-dimensional subcube has eigenvalue 2, which is greater than that of a ball of the same size, namely $\sqrt{3}$. Similarly for the 3-dimensional ball in the 7-hypercube. Also the $n/2 - \sqrt{n}$ radius ball has eigenvalue $n - 4$ (since $n/2 - \sqrt{n}$ is the first zero of the second Krawtchouk polynomial), and the $(n - 4)$ dimensional subcube is smaller; so by monotonicity (see [Fri93]) the ball here can also be beaten.} of very small or large balls that are not the Faber-Krahn minimizers.

**Question 12.1.** Given $\gamma \in (0, 1/2)$ is

$$\lim_{n \to \infty} \text{FK}_{3^n} \left(2^H_{2^\gamma} \right)/n = 2\sqrt{2(1 - \gamma)},$$

i.e. are balls asymptotically maximizers for the hypercube? If the answer is no, then according to the method of Corollary 8.6, we have an improvement to the first MRRW bound.

**Appendix A. Calculations for Coding Theory.**

In this section we derive some simple combinatorial bounds needed in our discussion of coding theory bounds.

Throughout this section we write $f(n) \approx g(n)$ if $(\log f(n))/(\log g(n)) \to 1$ as $n \to \infty$ (for example, $n \approx 2n$ but $n \not\approx n^2$).

**Lemma A.1.** If $\rho \in (0, 1/2]$ is fixed, and if any integer $n > 0$ we set \( r = r(n) = \lfloor \rho n \rfloor \), then

$$|B_r| \approx \left(\frac{n}{r}\right) \approx 2^{nh(\rho)},$$

where $|B_r|$ is the size of the ball of radius $r$ in the $n$-hypercube, and where

$$h(\theta) = -\theta \log_2 \theta - (1 - \theta) \log_2 (1 - \theta).$$

**Proof.** This is a very standard application of Stirling’s formula; see, for example, [vL99].

**Lemma A.2.** Let $\alpha \in (0, 1)$ be fixed. For any integer $n > 0$ set $k$ to be the even integer equal either to $\lceil \alpha n \rceil$ or to $\lfloor \alpha n \rfloor + 1$. Then

$$N_k(\mathbb{B}^n) \approx 2^{h(\beta_0)n - n^k(1 - 2\beta_0)^k},$$

where $\beta_0$ is the unique solution in $(0, 1/2)$ to the following equation

$$(1 - 2\beta_0)\log(\beta_0^{-1} - 1) = 2\alpha. \quad (A.1)$$
Proof. Since $A_n$ has eigenvalues $n - 2i$ with multiplicity $\binom{n}{i}$, we have

$$N_k(B^n) = \frac{1}{2^n} \sum_{i=0}^{n} \binom{n}{i} |n - 2i|^k.$$  

It follows that setting $B_i = \binom{n}{i}(n - 2i)^k$, we see that

$$\frac{N_k(B^n)}{n^i} \leq \max_{i=0, \ldots, n/2} \frac{B_k}{2^n} \leq N_k(B^n).$$

To find the $i$ maximizing $B_i$, we write

$$\frac{B_{i+1}}{B_i} = \frac{n - i}{i + 1} \left( \frac{n - 2(i + 1)}{n - 2i} \right)^k = \left( \frac{n - i}{i + 1} \right) e^{k log_e(1 - 2/(n - 2i))}.$$ 

Set $\beta = \beta_n = \alpha_0/n$ where $\alpha_0$ is the (an) $i \leq n/2$ maximizing $B_i$. Since $B_{i_0 + 1} < B_{i_0}$ we have

$$\left( \frac{1 - \beta}{\beta} + O(n^{-1}) \right) e^{-\frac{2\alpha}{n^2} + O(n^{-1})} < 1.$$ 

Hence

$$\frac{1 - \beta}{\beta} < e^{-\frac{2\alpha}{n^2} + O(n^{-1})}.$$ 

Similarly $B_{i_0 - 1} < B_{i_0}$, and the reverse inequality holds. Taking logarithms we conclude that

$$\log(\beta^{-1} - 1)(1 - 2\beta) = 2\alpha,$$

where $\beta$ is the lim sup and lim inf of $\beta_n$. But differentiation shows that

$$f(\beta) = \log(\beta^{-1} - 1)(1 - 2\beta)$$

has $f'(\beta) = -2 \log(\beta^{-1} - 1) - (1 - 2\beta)/(\beta - \beta^2)$ which is $< 0$ for $\beta \in (0, 1/2)$. It follows that there is a unique $\beta_0 \in (0, 1/2)$ that satisfies equation (A.1), and this $\beta_0$ is the limit of $\beta_n$.

\[\Box\]

Corollary A.3. For $\alpha, n, k$ as above we have

$$N_k(B^n) \approx n^k \left( \frac{\alpha + \omega(\alpha)}{e} \right)^{k/2},$$

where $\omega(\alpha)$ is a function of $\alpha$ with $\omega(\alpha) = O(\alpha^{3/2})$ as $\alpha \to 0$.

Proof. For $\beta = 1/2 - \epsilon$ with $\epsilon$ small we have

$$\log(\beta^{-1} - 1)(1 - 2\beta) = \log \left( \frac{1/2 + \epsilon}{1/2 - \epsilon} \right) 2\epsilon = 2\epsilon \log(1 + 4\epsilon + O(\epsilon^2)) = 8\epsilon^2 + O(\epsilon^3).$$

Hence for $\alpha$ small we have

$$2\alpha = 8\epsilon^2 + O(\epsilon^3) \text{ or } \sqrt{\alpha/4} = \epsilon + O(\epsilon^2) = \epsilon + O(\alpha).$$
Differentiation shows that
\[ h'(x) = \log_2(x^{-1} - 1), \quad h''(x) = \frac{-\log_2 e}{x - x^2}. \]
So \( h'(1/2) = 0 \) and \( h''(1/2) = -4\log_2 e, \) and
\[ h(1/2 - \epsilon) = 1 - 2(\log_2 e)\epsilon^2 + O(\epsilon^3). \]
It follows that
\[ 2^{-n} 2^{nh(\beta)} (n - 2\beta)^k \approx 2^{-n(\log_2 e)\epsilon^2 + O(ne^3)} n^k (1 - 2\epsilon)^k \]
\[ \approx e^{-2n(\alpha/4 + O(\alpha^{3/2}))} \alpha^n (2\sqrt{\alpha/4} + O(\alpha))^{\alpha n} \]
\[ \approx e^{-\alpha n/2} e^{O(\alpha^{3/2})} (n\sqrt{\alpha})^{\alpha n} (1 + \sqrt{\alpha})^{\alpha n} \approx n^k (\alpha/e)^{k/2} \left(1 + O(\sqrt{\alpha})\right)^{k/2}, \]
and the proposition is finished.

**Proof of Corollary 6.5:** Let \( G \) be the coset graph of \( C^\perp. \) Consider the largest odd integer, \( k, \) for which
\[ \sum_{i=0}^{k+2} \binom{n}{i} \geq 2^{\alpha n}. \]  
(A.2)
It follows that there are two points in \( G \) of distance \( \geq k + 3, \) and hence two edges of distance \( \geq k + 1. \) By Theorem 6.3, we have
\[ \lambda_2(A_G) \geq (N_{k-1}(\mathbb{B}^n))^{1/k}. \]
But by equation (A.2) and Lemma A.1 we have
\[ 2^{nh(k/n) + O(1)} \approx 2^{\alpha n}, \]
and thus
\[ k/n = h^{-1}(\alpha) + o_n(1) \]
(where \( o_n(1) \) denotes a function that tends to zero as \( n \to \infty). \) Since \( h^{-1}(\alpha) = \alpha/\log_2(1/\alpha) + O(\alpha) \) for \( \alpha \) small, Corollary A.3 then implies that
\[ \lambda_2/n \geq \sqrt{\frac{\alpha}{e \log_2(1/\alpha)}} + \omega(\alpha) + o_n(1), \]
where \( \omega(\alpha) = O(\sqrt{\alpha}). \) Now we use the fact that the minimum distance is \( (n - \lambda_2)/2. \)

**Proof of Corollary 7.3:** Let \( k \) be as in the previous proof, except that \( k \) is the largest odd integer such that
\[ N_{k+1}(\mathbb{B}^n) \geq n^k/|V_G|. \]
Then taking \(k\)-th roots and dividing by \(n\) yields that \(k = n\gamma + o(n)\) where

\[ \sqrt{\frac{\gamma}{\epsilon}} + \omega(\gamma) = 2^{-a/\gamma} \]

where \(\omega(\gamma) = O(\gamma)\) for \(\gamma\) small. Hence

\[ \gamma = \frac{2a}{\log_2(1/\alpha)} + O(\alpha), \]

for \(\alpha\) small. Now we follow as in the proceeding proof, except that here \(\gamma = k/n\) is, to first order, twice what it was in the previous proof; this factor of two changes the \(C\) from \(1/\sqrt{4\epsilon}\) to \(1/\sqrt{2\epsilon}\) here.

\[ \square \]

**Appendix B. A Calculus Proposition.**

In this section we prove Proposition 4.1.

Let \(f\) be defined at \(a_0\), and set \(\delta_0 = f(a_0)\). It suffices to show that \(\alpha_{\text{max}}(\delta_0) \leq a_0\).

For any \(\epsilon > 0\) near \(0\), fix an \(\eta > 0\). If

\[ \alpha_{\text{max}}(f(a_0 + \epsilon) + \eta) > a_0 + \epsilon, \]  

(B.1)

then there are codes \(C_i\) of length \(n_i \rightarrow \infty\) as \(i \rightarrow \infty\) such that \(\delta_{C_i} \geq f(a_0 + \epsilon) + \eta\) and

\[ \lim_{i \rightarrow \infty} \alpha_{C_i} > a_0 + \epsilon. \]

By passing to a subsequence we can assume that \(\alpha_{C_i} > a_0 + \epsilon\) for all \(i\). But then \(\delta_{\text{max}}\) exceeds \(f\) (by at least \(\eta\)) at the value \(a_0 + \epsilon\), which is impossible. So inequality (B.1) is impossible, meaning that

\[ \alpha_{\text{max}}(f(a_0 + \epsilon) + \eta) \leq a_0 + \epsilon. \]

Now let \(\eta = \eta(\epsilon) = \delta_0 - f(a_0 + \epsilon)\) and let \(\epsilon \rightarrow 0\). We conclude \(\alpha_{\text{max}}(\delta_0) \leq a_0\), and we are done.

**Appendix C. The First Eigenvalue of a Ball and Related Calculations.**

In this appendix we prove Proposition 8.5.

Since the size of the ball of radius \(n\gamma\) in \(\mathbb{B}^n\) is \(\approx 2^{n(h(\gamma))}\), we need only show that the ball of radius \(n\gamma\) has first eigenvalue at least

\[ 2n\sqrt{\gamma(1 - \gamma)} + o(n). \]

Let \(0\) denote the origin in \((\mathbb{F}_2)^n\), which is a vertex of \(\mathbb{B}^n\); the weight, \(|v|\), of a vertex, \(v\), of \(\mathbb{B}^n\) is its distance from \(0\), or the number of nonzero coordinates it has. Consider those functions, \(f\), on \(\mathbb{B}^n\) that depend only on the weight of the vertex. For such an \(f\), let \(f_{\text{nm}}\), the normalization of \(f\), be the function on \([0..n]\) such that

\[ f_{\text{nm}}(i) = f(v) \sqrt{\binom{n}{i}} \]

for any \(v\) with \(|v| = i\).

Then it is easy (and completely standard) to see that

\[ (A_G f)_{\text{nm}}(i) = \sqrt{i(n - i + 1)} f_{\text{nm}}(i - 1) + \sqrt{(i + 1)(n - i)} f_{\text{nm}}(i + 1), \]

where \(A_G f\) is the adjacency matrix of \(f\) on \(\mathbb{B}^n\).
for all $i$ (the coefficient of the right-hand-side vanishes for $f_{nm}$ at the values $-1$ and $n+1$). So under normalization the operator $A_G$ becomes a symmetric tridiagonal operator $\tilde{A}$ whose $i-1,i$ entry is $\sqrt{i(n-i+1)}$. It follows that if $i \in [\gamma n - \omega(n), \gamma n]$, where $\omega(n)$ is any function that is $o(n)$, then the $i-1,i$ entry is $$n\sqrt{\gamma(1-\gamma)} + o(n).$$

Hence, by monotonicity (see, e.g., [Fri93]), the first Dirichlet eigenvalue of the ball of radius $n\gamma$ is at least that of the path of length $\omega(n) + 1$ times $$n\sqrt{\gamma(1-\gamma)} + o(n).$$

But this path’s eigenvalue is well-known to be $2\cos(\pi/\omega(n))$, giving us a lower bound on the ball’s eigenvalue of $$2n\sqrt{\gamma(1-\gamma)} + o(n),$$ provided that $\omega(n)$ grows faster than $\sqrt{n}$ (e.g., we may take $\omega(n) = n^{3/4}$).

\[\square\]
